

Only the untaxed half of privateness predicts deconvolution error

99 strains, N2 excluded. Same total count as the earlier fit, split by whether each private marker falls inside that strain's own CaENDR divergent regions. Red line is a loess fit.

The design plane: benefit and tax are correlated, but loosely

Point size is privateness INSIDE divergent regions -- the taxed kind, which the left panels show does not predict error once the untaxed count is known. Upper left is what an optimiser wants and is largely empty: the most identifiable strains are also the most divergent. The exploitable variation is VERTICAL, within a tax level.
