

Sequencing depth: per sample and in aggregate

Reads subsampled to each depth and the deconvolution rerun, then compared with the published MIP-seq frequencies. A compares individual sample frequencies; B compares the per-strain slopes that Figure 1 plots, which average fifteen samples and so sit higher and saturate sooner. Spread between samples exceeds the effect of depth, and the worst sample does not improve with depth.

A Per-sample agreement against depth

One grey line per sample, 23 samples; dark line is the median across samples. Dashed line is the median full-depth agreement.

B Depth requirement

Slopes recomputed at each depth, then correlated with the MIP-seq slopes. Same y axis as A.
