

A Residue 96 is Ser or Thr across Caenorhabditis, and never Lys

Residues aligned to *C. elegans* 88-104 in every *Caenorhabditis* species whose ortholog has an HSP spanning the window; rows ordered by identity to *C. elegans*. The boxed columns are the N94-x-T96 sequon. Among the 14 species at or above the block-identity floor, residue 96 is Thr in 11, Ser in 1, and Lys in none, and the sequon is intact in 11. Only *C. doughertyi* changes residue 96 itself, to Ala; *C. afra* keeps Thr96 and loses Asn94, so it is a natural AxT, the construct in panel B. Two species below the floor appear to carry Lys96, but at 32% and 21% block identity those calls are not trustworthy.

B Removing the conserved sequon does not phenocopy 96K

N94A removes the sequon while leaving residue 96 alone, so it should phenocopy 96K if the glycan is what 96K destroys. It does not: AxT has no sequon and is fully resistant, so losing the sequon by removing Asn94 is harmless while losing it by substituting Lys96 costs 42 points. It is the lysine, not the missing glycan — which is what panel A's residue-96 column independently implies. Wilson 95% intervals; one plate per genotype at 50% *pos-1* RNAi, a different dose from Figure 4B, so these are not comparable with it.
